**ABSTRACT**

Process capability indices such as $C_p$ are used extensively in manufacturing industries to assess processes in order to decide about purchasing. In practice, the parameter for calculating $C_p$ is rarely known and is frequently replaced with estimates from an in-control reference sample. This article explores the optimal sample size required to achieve a desired error of estimation using absolute percentage error of different $C_p$ estimates. Moreover, some practical tools are created to allow practitioners to find sample size in different situations.

**KEYWORDS**

absolute percentage error; Phase I; process capability; six sigma; standard deviation

**Introduction and literature review**

Evaluating the capability of a manufacturing process is an important concept that has received much interest in six sigma, lean manufacturing and statistical process control (see Kotz and Johnson 1993; Kumar et al. 2006; Chen et al. 2010). In general, process capability compares the output of an in-control and steady process to the preset engineering specification limits by using *capability indices*. For example, the most popular capability index ($C_p$) forms the “ratio of the spread between the process specifications (the specification “width”) to the spread of the process values, as measured by 6 process standard deviation units (the process “width”)” (see NIST/SEMATECH e-Handbook of Statistical Methods 2012). Mathematically, $C_p$ is defined as:

$$C_p = \frac{\text{USL} - \text{LSL}}{6\sigma}, \quad [1]$$

where $\text{USL}$, $\text{LSL}$, and $\sigma$ are the upper specification limit, lower specification limit, the process standard deviation, respectively. Based on Eq. [1] and under the assumptions that the process is centered, $C_p$ can be used to easily quantify the % rejects of a process (see Table 1).

The calculations presented in Table 1 assume that the process standard deviation is known. In practice, however, process parameters such as $\sigma$ are rarely known, and they are estimated based on a suitable baseline sample. There are two possibilities for getting such estimates: (1) based on a Phase I control chart; or (2) from a dedicated baseline sample. For our purposes, these two scenarios are identical since the effect of estimation error on $C_p$ is solely based on sample size. When $\sigma$ is to be estimated, process capability would be defined as:

$$\hat{C}_p = \frac{\text{USL} - \text{LSL}}{6\hat{\sigma}}, \quad [2]$$

where $\hat{\sigma}$ represents any appropriate estimator for $\sigma$. Note that any error in estimating $\sigma$ would result in an incorrect estimator of the true process capability. The problem of estimating $\sigma$ can be divided into two parts: (a) what is the best (robust, unbiased, and/or min variance) estimator for $\sigma$? (b) What sample size is needed such that the effect of estimation error can be neglected? The selection of the best estimator for sigma in part a was considered by several researchers including Kirmani, Kocherlakota, and Kocherlakota (1991), Derman and Ross (1995), Ravindra Khattree (1999), and Mahmoud et al. (2010). In the context of the control charting literature, the effect of parameter estimation on a control chart’s properties has been reviewed by Jensen et al. (2006) and Jones-Farmer et al. (2014). These articles show that estimated parameters can have a significant effect on both the in-control and out-of-control performance of control charts, especially with small to moderate sample sizes.

For part b, Franklin (1999), Zimmer, Hubele, and Zimmer (2001), Pearn and Ming-Hung (2003), and Wua and Kuo (2004) have investigated the sample sizes needed by considering a lower confidence interval approach as a basis for the decision. They have assumed that the process is in-control (or steady) and its output is normally distributed (or an appropriate transformation can be applied to not violate the normality assumption). It should be noted that these articles use the ratio of actual process capability over the estimated one \( \left( \frac{\bar{C}_p}{\hat{C}_p} \right) \) and offer sample size recommendation based on the associated confidence interval. Unfortunately, this approach is somewhat limiting in practice. We highlight three potential issues in using the ratio \( \left( \frac{\bar{C}_p}{\hat{C}_p} \right) \) as a basis for decision-making.

(a) The interpretation of APE is much simpler than the aforementioned ratio. Specifically, the use of APE allows us to consider the estimation error as a function of sample size.

(b) We consider APE as a random variable as detailed later in this article. This allows us to consider both the expected value and the standard deviation of APE when calculating the sample size. It is important to note that the ability to calculate the standard deviation of the APE allows us to consider the between samples variation (each typically considering one baseline sample) in estimating \( C_p \).

It should be noted that we consider the calculation of sample size in the case of single and multiple sampling procedures, as well as through using different estimators of \( \sigma \). To ensure the broad reach of this approach, we provide a toolkit to allow practitioners to find appropriate sample size based on simple criteria (see the Appendix for more details).

In this article, the process is supposed to be in-control, centered and the quality characteristic follows a normal distribution. The next section presents definitions for the expected value of APE and its standard deviation, and the procedure for calculating the sample size based on the different estimators for \( \sigma \).

In the “Results and discussion” section, we present numerical results to highlight how our approach can be used in practice. Finally, in the last section, we offer some concluding remarks. The mathematical derivations, codes used, and an overview of the practitioner toolkit are provided in Appendices A, B, and C, respectively.

Methodology

The single sampling case

In this section, we consider scenarios where practitioners attempt to estimate the process standard deviation based on a single baseline sample. In particular, two
different estimators for $\sigma$ are discussed; $s$ and $s/c_4$. Below, we show how practitioners can use the APE statistic to determine the sample size needed such that the effect of any estimation error on $C_p$ can be neglected.

$s$ as an estimator for $\sigma$

The sample standard deviation, $s$, is widely used to estimate the population/process standard deviation. Let $i = 1, 2, \ldots$ be an independent sample of size $n$ drawn from a process that is normally distributed with constant, but unknown parameters ($\mu$, $\sigma^2$). Then, $s$ can be calculated as:

$$s = \sqrt{\frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{n-1}}, \quad [3]$$

where $\bar{x}$ is the sample mean. When $s$ is used to estimate $\sigma$, Eq. [2] can be re-written as:

$$\hat{C}_p = (USL - LSL) / 6s. \quad [4]$$

Note that we added the subscript $s$ to denote that the use of the sample standard deviation. In this case, the Absolute Percentage Error for $C_p$ can be defined as:

$$APE_s = \frac{\hat{C}_p - C_p}{C_p} = \left| \frac{USL - LSL}{6s} - \frac{USL - LSL}{6\sigma} \right| = 1 - \frac{\sigma}{s}. \quad [5]$$

Since APE$_s$ is a r.v., we can define its expected value and standard deviation based on $U = \frac{(n-1)s^2}{\sigma^2} \sim \chi^2_{n-1}$. Then the expected value and standard deviation of the APE$_s$ can be formulated as:

$$APE_s = f (U) = \left| 1 - \left( \frac{U}{n-1} \right)^{-\frac{1}{2}} \right|, \quad [6]$$

$$E (APE_s) = \int_{0}^{\infty} f (U) g (U) \ du, \quad [7]$$

$$SD (APE_s) = (E (APE_s^2) - E^2 (APE_s))^\frac{1}{2}. \quad [8]$$

Note that $g(U)$ is the probability density function for $U$ based on the $\chi^2_{n-1}$ distribution. Based on the Eqs. [6]–[8], we can define a function that allows a practitioner to find an appropriate sample size based on a pre-specified error criterion as shown in Eq. [9]:

$$P (APE_s < \text{Max APE}) > 1 - \alpha, \quad [9]$$

where $1 - \alpha$ represents a confidence level such that $0 < \alpha < 1$. Note that the choice of $\alpha$ represents the risk threshold that the practitioner is willing to take. For example, $\alpha = 0.05$ would mean that in 95% of the samples APE will be smaller than the Max APE. In Eq. [9], for a given Max APE (representing a user’s required level of accuracy) and a pre-defined $\alpha$ value, $n$ is the only unknown. Thus, Eq. [9] can be used to obtain the smallest sample size that meets these two criteria. The section titled “Results for the single sampling scenarios” provides numerical solutions for different combinations of Max APE and $\alpha$.

$s/c_4$ as an estimator for $\sigma$

It is well documented that $s$ is a biased estimator for the population standard deviation, and thus, a correction factor $c_4$ is often used to eliminate the bias (see, e.g., Montgomery Runger, and Hubelle 2009; Mahmoud et al. 2010). Note $c_4$ is a function of $n$:

$$c_4 = c_4 (n) = \left( \frac{2}{n-1} \right)^{\frac{1}{2}} \frac{\Gamma \left( \frac{n}{2} \right)}{\Gamma \left( \frac{n-1}{2} \right)}. \quad [10]$$

In this situation, $\hat{s} = s/c_4$ and $\hat{C}_p = \frac{USL - LSL}{6\hat{s}}$. By substituting $s$ by $s/c_4$ in Eqs. [5]–[9], one could easily obtain an expression where (APE$_{\hat{s}} < \text{Max APE} > 1 - \alpha$. This expression can then be used to obtain the smallest sample size that meets Max APE and a pre-defined $\alpha$ value given that $s/c_4$ is used to estimate the process standard deviation. For the sake of completion, we provide the detailed mathematical expressions in the Appendix.

Using multiple samples for estimating the process standard deviation

Similar to the previous section “The single sampling case,” we provide details for two commonly used estimators for $\sigma$ when multiple samples are used. The details for using these estimators are provided below.

Using the pooled sample standard deviation ($5p$)

Let $x_{ij}$ ($i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, n$) be $m$ independent baseline samples of size $n$ drawn from a process that is normally distributed with constant, but unknown parameters ($\mu$, $\sigma^2$). The pooled sample standard deviation, $S_p$, can be used to estimate the process standard deviation:

$$S_p = \left( \frac{1}{m} \sum_{i=1}^{m} s_i^2 \right)^{\frac{1}{2}} = \left( \frac{1}{m(n-1)} \sum_{i=1}^{m} \sum_{j=1}^{n} (x_{ij} - \bar{x}_i)^2 \right)^{\frac{1}{2}}. \quad [11]$$
Consequently, $C_p$ and the APEs can be calculated as:

$$\overline{C_p}_s = \frac{\text{USL} - \text{LSL}}{6S_p}, \quad \text{and} \quad \text{APE}_s = \left| \frac{C_p - \overline{C_p}_s}{C_p} \right| = \left| \frac{\text{USL} - \text{LSL}}{6\sigma} - \frac{\text{USL} - \text{LSL}}{6S_p} \right| = \left| 1 - \frac{\sigma}{S_p} \right|. \quad [12]$$

Expressions for expected value and standard deviation of APEs can be derived by replacing $s$ by $S_p$ in Eqs. [6]–[8] and using $U = \frac{m(n-1)S_p^2}{\sigma^2} \sim \chi^2_{m(n-1)}$. Based on this information, we can now define a function that allows us to calculate the required sample size for a given $\alpha$ and Max APE:

$$P(\text{APE}_s < \text{Max APE}) > 1 - \alpha. \quad [13]$$

**Using $\frac{s}{c_4}$ for estimating the process standard deviation**

Another approach for estimating $\sigma$ when multiple baseline samples are drawn can be obtained by using the estimator $\hat{\sigma} = \frac{\bar{s}}{c_4}$, which can be seen as the multiple sample extension for the method highlighted in the section titled “$s/c_4$ as an estimator for $\sigma$”. Similar to our discussion for $S_p$, let $x_{ij}$ ($i = 1, 2, \ldots, m$ and $j = 1, 2, \ldots, n$) be $m$ independent samples of size $n$ from a $N(\mu, \sigma^2)$ process. $\bar{s}$ is defined as:

$$\bar{s} = \frac{1}{m} (s_1 + s_2 + \cdots + s_m), \quad [15]$$

where $s_i$ is the standard deviation for sample $i$, which can be calculated by Eq. [3]. By replacing $s$ by $\bar{s}/c_4$ in Eqs. [4] and [5], we can obtain the following:

$$\overline{C_p}_{\bar{s}} = \frac{\text{USL} - \text{LSL}}{6\frac{\bar{s}}{c_4}}, \quad \text{and} \quad [16]$$

and

$$\text{APE}_{\bar{s}} = \left| \frac{C_p - \overline{C_p}_{\bar{s}}}{C_p} \right| = \left| \frac{\text{USL} - \text{LSL}}{6\frac{\bar{s}}{c_4}} - \frac{\text{USL} - \text{LSL}}{6S_p} \right| = \left| 1 - \frac{\sigma}{\bar{s}} \right|. \quad [17]$$

Similar to our discussion in “The single sampling case,” $\text{APE}_{\bar{s}}$ is a random variable. To calculate its expected value and standard deviation, let $Q = \frac{\hat{\sigma}}{\sigma}$ such that the distribution of $Q$ is independent of $\sigma$. Based on the derivations in Patnaik (1950) and Chen (1998), $Q$ is a scaled chi random variable $\frac{Q\sqrt{v}}{\Gamma^2}$, and the probability density of $\frac{Q\sqrt{v}}{\Gamma^2}$ is:

$$g(q, v, c) = \frac{2}{c} \left( \frac{q}{c} \right)^{\frac{v+1}{2}} \exp \left( -\frac{v}{2} \left( \frac{q}{c} \right)^2 \right), \quad [18]$$

where $v = (-2 + 2\sqrt{1 + 2t})^{-1}$ and $c = 1 + \frac{1}{4v} + \frac{3v}{12v^2} - \frac{5}{128v^2}$ $\sigma$. To calculate $v$ and $c$, we follow the approach of Patnaik (1950) and Chen (1998) who used $r = (-2 + 2\sqrt{1 + 2M_1})^{-1}$, $t = M_1 + \frac{1}{16r^2}$, and $M_1 = \frac{\nu_0\nu_1^2}{\nu_0(\nu_1)^2}$. Therefore, the APE, expected value and standard deviation can be obtained as:

$$\text{APE}_{\bar{s}} = f(Q) = \left| 1 - \frac{1}{\bar{Q}} \right|, \quad [19]$$

$$E\left(\text{APE}_{\bar{s}}\right) = \int_0^\infty f(Q) g(Q) \text{dq}, \quad [20]$$

$$\text{SD}\left(\text{APE}_{\bar{s}}\right) = \sqrt{E\left(\text{APE}_{\bar{s}}^2\right) - E^2\left(\text{APE}_{\bar{s}}\right)}. \quad [21]$$

Note that $g(Q)$ in Eq. [20] represents the probability density function for Q. With Eqs. [19]–[21], we can obtain a function that allows us to calculate the required sample size for a given $\alpha$ and Max APE. This function is identical to that in Eq. [14]; however, APEs are substituted with $\text{APE}_{\bar{s}}$.

**Results and discussion**

In this section, we present the results for the scenarios when practitioners use one baseline sample and multiple baseline samples to estimate the process standard deviation. In each subsection, we first present the expected value of APE and its standard deviation based on different estimators and sample sizes. Those values are calculated based on the formulas in the “Methodology” section and the R codes in the Appendix. Then, we provide some numerical simulations to highlight the between samples variation in APE based on the prescribed sampling plan. We then provide our sample size recommendations based on numerical solutions for the derived functions for $n$ for a given $\alpha$ and Max APE.

**Results for the single sampling scenarios**

For a single sampling plan, we provide the E(APE) and SD(APE) for both $s$ and $\bar{s}$ in Table 2 by using the formula provided in the Appendix. The results demonstrate that as the sample size increases, both E(APE) and SD(APE) decrease. Moreover, smaller E(APE) and SD(APE) values are obtained by using $\bar{s}$ instead of $s$.

</table>

In other words, \( \hat{\sigma} \) can be more efficient than \( s \) especially for small sample sizes. It should be noted that the use of the often recommended sample sizes of 30 to estimate the process standard deviation (see Montgomery (2014)) or 50 (see SEMATECH e-Handbook of Statistical Methods (2012)) result in E(APE) of at least 8% with a standard deviation that is greater than 6.5%. This means that the estimated values for \( C_p \) can vary as much as 25–30% from their true value with these sample sizes, which can result in practitioners drawing wrong conclusions about the capability of their process.

To highlight the variation in APE, consider a situation where a practitioner draws 100 samples of size \( n \) to estimate the process standard deviation (either by using \( s \) or \( s/c_4 \)). For the sake of this discussion, let us assume that the practitioner uses \( \hat{\sigma} = s \). Since we are focusing on the single sample scenario here, each sample would...
result in one estimate for $C_p$. We depict the variation in the APEs associated with this simulation scenario in Figure 1. Note that the purpose of this simulation is to assist readers in visualizing the decrease in APE when $n$ is larger. As expected from Table 2, the variation is reduced as the sample size is increased. Additionally, by setting the value of the Max APE = 0.05, we can visualize the function $P(APE_s < \text{Max APE})$. From the figures, it is clear that the number of practitioners (i.e., points) that are above the Max APE is reduced when $n$ increases. Additionally, it becomes less likely to get larger values for APE. This result is one of the contributions of this article since previous work did not consider the variation in their error metric as a function of $n$.

Based on Figure 1 and Table 2, we present the smallest sample size needed for different values of Max APE and $\alpha = 0.05$ in Table 3. Note that the sample sizes needed are much larger than what is used in practice if one were to use $\alpha = 0.05$. However, even if different values of $\alpha$ were to be used the required sample size will still be large as shown in Figure 2. Note that the sample size needed varies from 417 to 545 to 774 for $\alpha = 0.15$, $\alpha = 0.10$, and $\alpha = 0.05$, respectively.

### Results for when multiple samples are used

The results for $E(\text{APE})$ and $SD(\text{APE})$ for both $S_p$ and $\bar{s}/c_4$ used (based on different combinations of $m$ and $n$) to estimate $\sigma$ are presented in Table 4. Similar to Table 1, the values for $E(\text{APE})$ and $SD(\text{APE})$ decrease as the number of samples ($m$) and/or the sample size ($n$) increase. Additionally, the use of $S_p$ is more efficient than $\bar{s}/c_4$, especially when $N = m \times n$ is small, since $E(\text{APE})$ and $SD(\text{APE})$ for $S_p$ are smaller than the corresponding values of $\bar{s}/c_4$. As expected, the values for $E(\text{APE})$ and $SD(\text{APE})$ are dependent on both $m$ and $n$, i.e., the values are different for the following two scenarios: (a) $n = 5$, $m = 20$ and (b) $n = 10$ and $m = 10$.

To highlight the variation in APE, consider a situation where a practitioner draws 100 samples of size $n$ to estimate the process standard deviation (either by using $S_p$ or $\bar{s}/c_4$). For the sake of this discussion, let us assume that the practitioner uses $\hat{\sigma} = s_p$. Since we are focusing on the multiple sample scenario here, each sample would result in one estimate for $C_p$.

Similar to Figure 1, we depict the variation in the APEs associated with 100 simulation runs where a practitioner draws $m$ samples of size $n$ in Figure 3. From Table 4, the variation is reduced as $m$ and/or $n$ increases. By setting the value of the Max APE = 0.05, we can visualize the function $P(APE_{sp} < \text{Max APE})$. From the figures, it is clear that the number of points that are above the Max APE is reduced when $m$ and/or $n$ increases. These results are consistent with Figure 1 and provide insights into why practitioners should consider the variation in the APE.

In Table 5, we provide candidate $n$ and $m$ values when $S_p$ and $\bar{s}/c_4$ are used to estimate $\sigma$. For small values of $n$, the total number of samples required is much smaller when $S_p$ is used. However, $m$ converges for larger values of $n$. The code provided in the Appendix allows the reader to examine solutions for different values of Max APE and $\alpha$.

Concluding remarks

In this article, we investigated the effect of estimation error on the process capability index ($C_p$) using four different estimators of the process standard deviation. We propose using the expected value and standard deviation of the absolute percentage error (APE) to quantify the variation that is seen from one practitioner to another if they were to use a single sample of size $n$ (or $m$ samples of size $n$) to estimate the process standard deviation. From our calculations, there are four main conclusions one can obtain from this article.

(a) The sample sizes required are generally much larger than the current ones used in industry. For example, the recommendation from the NIST/SEMATECH e-Handbook of Statistical Methods is to use $n = 50$. When one sample is used to estimate $\sigma$, we recommend $n$ to be in the hundreds based on Table 3. This recommendation would result in increasing the current sample size used in industry by a factor of 10. However, it will minimize the effect of sampling error on $C_p$.

(b) It is more efficient to use a single sample of size $N$ than $m$ samples of size $n$ (where $N = m \times n$). This can be seen by comparing results from Tables 3 and 5.

(c) If the practitioner has no preference for how to estimate the process standard deviation from a sample of size $n$, using the estimator $s/\sigma_4$ is somewhat preferred over $s$ since the standard deviation of the APE is smaller.

(d) The use of APE with the two decision criteria, Max APE and $\alpha$, provides a simple method to characterize the between samples variation when estimating $C_p$. Practitioners can easily understand and visualize the impact of their sample size selection on the calculation of $C_p$ by using our tool.

It should be noted that our work assumes that the process output is centered and is normally distributed. These two assumptions are not restrictive. Steiner and Mackay (2005, Ch. 15) provide an algorithm for moving the process center. There are several transformations that can be used to transform non-normal data (e.g., Box-Cox transformation). Perhaps more importantly, these are the assumptions behind using $C_p$ for determining process capability. In this article, our goal is to highlight what sample size is needed (given these assumptions are true) so that the effect of estimation error can be neglected. Future work can address extending our methodology to other process capability indices. It should be noted however that other indices often require the estimation of multiple parameters so the solutions for these should be based on numerical simulations. This might make the development of a tool for practitioners more difficult.

About the authors

Zahra Sedighi Maman is a Ph.D. student in the Department of Industrial and Systems Engineering at Auburn University. Her research interests are in the areas of analytics, data visualization, statistical process control, and quality engineering.

W. Wade Murphy is a Master student in the Department of Industrial and Systems Engineering at Auburn University. His research interests are in: computer programming, data analytics, simulation of complex systems, manufacturing systems design, and operations research.

Saeed Maghsoudloo is a professor emeritus in the Department of Industrial and Systems Engineering at Auburn University. His research interests and publications are in the areas of design of experiments, off-line and on-line quality control, multivariate analysis, regression/correlation and time-series analysis, reliability engineering, and nonparametric statistics. He is a member of ASA and ASQ and is an associate editor of IIE Transactions and the Journal of Manufacturing Systems and is a reviewer for numerous national and international journals. He is a registered professional engineer in the state of Alabama and is a past member of the editorial board of Quality and Reliability Engineering of IIE Transactions.

Hannane Haj Ahmad received her MS in Industrial Engineering at Azad Tehran Shomal University, Tehran, Iran. She is currently a research assistant at Iran University of Science and Technology, Tehran, Iran. Her research interests are in reliability engineering, statistical process control, and applied statistics.

Fadel M. Megahed is an assistant professor in the Department of Industrial and Systems Engineering at Auburn University, Auburn, Alabama. His current research focuses on creating new tools to store, organize, analyze, model, and visualize the large heterogeneous data sets associated with modern manufacturing, healthcare and service environments. He is a member of ASQ.

Appendix

Finding the sample size based on the different estimators

When $s$ is used to estimate $\sigma$

In the section titled “$s$ as an estimator for $\sigma$” we presented Eq. [9] where we stated that an appropriate sample size based on a pre-specified error criterion can be obtained. In this subsection of the Appendix, we start with this equation and show the mathematical manipulations needed to solve for $n$. Our final equation has $n$ as the only unknown and could be solved using any statistical package. We present our R code for solving this formulation in the next section:

$$P\left(APE_s < Max\ APE > 1 - \alpha\right), \quad [A1]$$

$$P\left(-Max\ APE < \frac{Cp - \hat{C}p}{Cp} < Max\ APE\right) > 1 - \alpha, \quad [A2]$$

By substituting $C_p$ and $\hat{C}_p$ by their corresponding values that are based on Eqs. [1] and [2] and replacing $\hat{\sigma}$ by $s$, we obtain:

$$P\left(-Max\ APE < \frac{USL - LSL}{6s} - \frac{USL - LSL}{6\sigma} < Max\ APE\right) > 1 - \alpha. \quad [A3]$$

This will give us:

$$P\left(\frac{1}{1 + Max\ APE} < \frac{s}{\sigma} < \frac{1}{1 - Max\ APE}\right) > 1 - \alpha. \quad [A4]$$

$$P\left(\frac{1}{(1 + Max\ APE)^2} < \frac{s^2}{\sigma^2} < \frac{1}{(1 - Max\ APE)^2}\right) > 1 - \alpha. \quad [A5]$$

By substituting $\frac{s^2}{\sigma^2}$ by its corresponding distribution function, we obtain:

$$P\left(\frac{n - 1}{(1 + Max\ APE)^2} < \chi^2_{n-1} < \frac{n - 1}{(1 - Max\ APE)^2}\right) > 1 - \alpha. \quad [A6]$$

Finally, by determining the $\alpha$ and Max APE, we can solve the equation to find the sample size.

$$\frac{s}{c_4}$$
Similar to our discussion for \( s \), let us consider Eq. [10] in the section titled “s/c4 as an estimator for \( \sigma^2 \)” to find the appropriate sample size based on a pre-specified error criterion. Then in this subsection of the appendix, we will have:

\[
P\left( \text{APE}_{\frac{s}{c_4}} < \text{Max APE} \right) > 1 - \alpha, \quad \text{and} \quad \text{[A7]}
\]

\[
P\left( - \text{Max APE} < \frac{Cp - \widehat{Cp}}{Cp} < \text{Max APE} \right) > 1 - \alpha.
\]

By substituting \( C_p \) and \( \widehat{Cp} \) by their corresponding values, and replacing \( \hat{\sigma} \) by \( \frac{s}{c_4} \), one could easily obtain:

\[
P\left( - \text{Max APE} < \frac{\frac{USL-LSL}{6\sigma}}{\frac{USL-LSL}{6\sigma}} < \text{Max APE} \right)
> 1 - \alpha. \quad \text{[A8]}
\]

Then:

\[
P\left( \frac{c_4}{1 + \text{Max APE}} < \frac{s}{\sigma} < \frac{c_4}{1 - \text{Max APE}} \right) > 1 - \alpha. \quad \text{[A9]}
\]

\[
P\left( \left( \frac{c_4}{1 + \text{Max APE}} \right)^2 < \frac{s^2}{\sigma^2} < \left( \frac{c_4}{1 - \text{Max APE}} \right)^2 \right) > 1 - \alpha. \quad \text{[A10]}
\]

By substituting \( \frac{s^2}{\sigma^2} \) by its corresponding probability density function, we obtain:

\[
P\left( (n-1) \left( \frac{c_4}{1 + \text{Max APE}} \right)^2 < \chi^2_{n-1} < (n-1) \right.
\times \left( \frac{c_4}{1 - \text{Max APE}} \right)^2 > 1 - \alpha. \quad \text{[A11]}
\]

By considering Max APE and a pre-defined \( \alpha \) value this final equation has \( n \) as the only unknown and could be solved using any statistical package.

**When \( \frac{s}{c_4} \) is used to estimate \( \sigma \)**

Similar to our procedure for \( s \), consider Eq. [14] in the section titled “Using the pooled sample standard deviation (Sp)” to find the sample size. In this case, we start with this Eq and show the mathematical manipulations needed to solve for \( n \).

\[
P\left( \text{APE}_{\frac{s}{c_4}} < \text{Max APE} \right) > 1 - \alpha, \quad \text{and} \quad \text{[A12]}
\]

\[
P\left( - \text{Max APE} < \frac{Cp - \widehat{Cp}}{Cp} < \text{Max APE} \right) > 1 - \alpha.
\]

By substituting \( C_p \) and \( \widehat{Cp} \) by their corresponding values and replacing \( \hat{\sigma} \) by \( s_p \), we obtain:

\[
P\left( - \text{Max APE} < \frac{\frac{USL-LSL}{6\sigma}}{\frac{USL-LSL}{6\sigma}} < \text{Max APE} \right)
> 1 - \alpha. \quad \text{[A13]}
\]

This will give us:

\[
P\left( \frac{1}{1 + \text{Max APE}} < \frac{s_p}{\sigma} < \frac{1}{1 - \text{Max APE}} \right)
> 1 - \alpha. \quad \text{[A14]}
\]

Then by substituting \( \frac{s_p^2}{\sigma^2} \) by its corresponding distribution function, we have:

\[
P\left( \frac{m(n-1)}{(1 + \text{Max APE})^2} < \chi^2_{m(n-1)} < \frac{m(n-1)}{(1 - \text{Max APE})^2} \right)
> 1 - \alpha. \quad \text{[A15]}
\]

This final equation has \( n \) and \( m \) as the only unknown and could be solved using any statistical package.

**When \( \frac{s}{c_4} \) is used to estimate \( \sigma \)**

Here, we will follow the same steps as when \( s \) is used to estimate \( \sigma \).

We will use Eq. [17] to find the appropriate sample size:

\[
P\left( \text{APE}_{\frac{s}{c_4}} < \text{Max APE} \right) > 1 - \alpha, \quad \text{and} \quad \text{[A17]}
\]

\[
P\left( - \text{Max APE} < \frac{Cp - \widehat{Cp}}{Cp} < \text{Max APE} \right) > 1 - \alpha,
\]

By substituting \( C_p \) and \( \widehat{Cp} \) by their corresponding values and replacing \( \hat{\sigma} \) by \( \frac{s}{c_4} \), we have:

\[
P\left( - \text{Max APE} < \frac{\frac{USL-LSL}{6\sigma}}{\frac{USL-LSL}{6\sigma}} < \text{Max APE} \right)
> 1 - \alpha. \quad \text{[A18]}
\]

This will give us:

\[
P\left( \frac{1}{1 + \text{Max APE}} < \frac{s}{c_4\sigma} < \frac{1}{1 - \text{Max APE}} \right)
> 1 - \alpha. \quad \text{[A19]}
\]
By substituting $\frac{\text{Max APE}}{\sigma}$ by its corresponding distribution function, we obtain:

$$P \left( \frac{1}{1 + \text{Max APE}} \leq \frac{c \chi^2_v}{\sqrt{v}} \leq \frac{1}{1 - \text{Max APE}} \right) > 1 - \alpha.$$  \[A20\]

This final equation allows us to calculate the required sample $n$ and $m$ for a given $\alpha$ and Max APE.

**R codes to find the sample size based on the different estimators**

The code used to generate the results discussed in this article uses the R Programming Language (https://www.r-project.org/). To allow researchers to replicate/extend our work, we provide the following link to our code: https://github.com/zahrame/Process-Capability-tool. The reader should note that this shared folder contains four different files; one corresponding to each estimator for $\sigma$. To use the code, one should specify the max APE and $1 - \alpha$ for the single sample situation. The code will present a suitable sample size based on these constraints. For the multiple samples scenario, the user should also specify either $m$ or $n$ and solve for the other.

**An overview of the practitioner’s toolkit for sample size determination**

Here, we present an excel-based tool that practitioners can use for calculating the sample size (or number of samples) for the different estimators of $\sigma$. We provide the Excel based tool at: https://github.com/zahrame/Process-Capability-tool. An overview of the functionality of the tool is provided below to serve as a help document for practitioners.
In the landing page of the tool, we ask the user to select the estimator that they want to use for \( \sigma \). The four estimators are represented by different buttons as shown in Figure A1. Once the user clicks on any of the four buttons, it will display a particular user-form where he/she can input data for that button and calculate the sample size. For multiple samples, they can also calculate number of samples if they were to provide the sample size as an input (otherwise they should provide the number of samples and solve for the sample size). As an example, we show the user-form generated by selecting the pooled estimator in Figure A2. Based on this information, practitioners can easily determine the sample size needed for their given application. Note that we assume that practitioners have access to Microsoft Excel and that they are familiar with the different estimators for the standard deviation. We believe that these assumptions are reasonable based on our experience with quality practitioners in advanced manufacturing domains.
